River Seismic Noise

Hillslope Processes

Dedicated Experiments

What is a transient event?

- The burst of high-frequency seismic energy reveals an intense sediment transport in gullies or landslide scars
- The induced erosion may alter the stability of slopes (stream incision, bank erosion...) and may trigger a mass movement (*cf.* the Ramche Debris Flow)
- The debris removal will thus contribute to the generation of high-frequency seismic energy
- These episodes of seismic noise are clearly consistent with peaks of sediment load presumably associated to landslides
- Towards a seismic measurement of eroded volumes, sediment input and denudation rates ?

River Seismic Noise

Hillslope Processes

Dedicated Experiments

Conclusions & future works

- Analysis of high-frequency river seismic noise depicts a potential to monitor spatially and continuously the bed load transport
- Location of sediment transport along rivers can be performed using cross-correlation of seismic noise at pairs of stations
- High-frequency seismic noise also reveals interesting features for the detection and the location of debris flows
- Such a monitoring of surface processes can lead to seismically measure erosion and its spatio-temporal variations
- Dedicated experiments are required to translate seismic signals into geomorphic observations like sediment transport, erosion rates...
